ABSTRACT

We investigate the radio emission of $\sim 185,000$ quiescent (optically unclassifiable) galaxies selected from the Sloan Digital Sky Survey (SDSS). By median-stacking FIRST cutouts centered on the optically-selected sources, we are able to reach flux densities down to the 10s of μJy . The quiescent galaxy sample is composed of two subgroups inhabiting vastly different regimes: those targeted for the SDSS MAIN Galaxy Sample ($\sim 55\%$), and those targeted for the Luminous Red Galaxy (LRG) sample ($\sim 45\%$). To investigate the star-formation of these quiescent galaxies, we calibrate a radio-SFR conversion using a third sample of star-forming galaxies. We confirm a tight power-law dependence for the star-forming (SF) sample, where $L_{1.4\text{GHz}} \sim (\text{SFR})^{1.37}$. Comparing this SFR-indicator with indicators in the optical and UV, we derive conflicting SFR estimates for the MAIN sample quiescent galaxies. These radio-derived SFRs intersect those calculated using the 4000-Å break (D4000) around an SFR of $1 M_{\odot} \text{ yr}^{-1}$ and agree to within a factor of 3 over the range of SFRs. However, we find that the radio-derived SFRs are too high relative to the SFRs estimated for similar populations of galaxies using analysis of UV emission, implying either contamination of the radio by Active Galactic Nuclei (AGN) or incomplete dust modeling. If AGN activity is dominant in these galaxies, then a relation between AGN radio luminosity and galaxy mass is required to explain the observed trends. For the LRGs, on the other hand, we find the radio luminosity to be relatively high (compared to the SF galaxies) and independent of SFR as derived from D4000, indicating an AGN component dominates their radio emission. AGN-based radio emission often implies the existence of radio jets, providing evidence of a mechanism for low-level feedback in these quiescent LRGs.

Subject headings:

1. INTRODUCTION

For normal galaxies – those not deriving their radio luminosity from a nuclear “monster” – the radio emission is a probe of recent star-formation (Condon 1992). In particular, the emission below 30 GHz is thought to be largely dominated by synchrotron radiation from ultra-relativistic electrons accelerated in supernova remnants. As most of the remnants responsible for this non-thermal emission result from massive, short-lived stars, the resulting radio emission tracks recent star-formation. Further evidence in favor of this claim comes from the existence of a tight radio/far-infrared (FIR) correlation, which has been found to hold over several orders of magnitude in radio luminosity (Harwit & Pacini 1975; Cram et al. 1998; Yun et al. 2001).

The complex astrophysics connecting the integrated radio emission to supernova explosions has led to a historical preference for other methods. Normal galaxies, with quite low radio flux densities, are also usually below the sensitivity of typical wide-area radio surveys. Alternative indicators of star-formation rate (SFR) include

continuum emission in both the near-ultraviolet and the far-infrared (Donas & Deharveng 1984; Harper & Low 1973). Another common diagnostic, referred to later in this paper, is the use of integrated emission-line fluxes (Cohen 1976; Kennicutt 1983). (For additional indicators, see the excellent review by Kennicutt (1998).)

However, star-formation is not the only process that produces radio emission; Active Galactic Nuclei (AGN) can also be strong emitters in the radio. This ambiguity has led to much debate, particularly for the less well-studied sub-mJy population. On the one hand, there is a widely held belief that the population of sub-mJy radio sources is dominated by star-forming galaxies (Condon 1984; Windhorst et al. 1985; Kron, Koo, & Windhorst 1985; Wall & Jackson 1997). For example, using an infrared-selected sample, Boyle et al. (2007) found the radio/FIR correlation persisted down to μJy flux densities, and they conclude that the radio emission of these sources is dominated by star-formation (with redshift still unknown). However, the hypothesis that there are a significant number of AGN at these low flux densities has recently received some attention as well. Jarvis & Rawlings (2004), in a theoretical paper, suggested that the flattening in the observed counts of the normalized local luminosity function below $S \sim 1 \text{ mJy}$

is due to a “radio-quiet” AGN population. In a follow-up observational study, Simpson et al. (2006) concluded that radio-quiet AGN comprise a significant population below $\sim 300 \mu\text{Jy}$, and that they may, in fact, dominate.

Studying the general properties of the low-luminosity radio population, however, has proven to be difficult; the perennial trade-off between coverage area and depth discourages surveys that are both deep and wide. In this paper, we take advantage of the overlapping coverage of two surveys, FIRST (Faint Images of the Radio Sky at Twenty Centimeters) and the SDSS (Sloan Digital Sky Survey), to study the faint radio emission of a large sample of optically-normal (“quiescent”) galaxies. By selecting galaxies with no strong optical emission lines from star-formation or AGN activity, we construct a sample that is likely to be inherently radio-quiet in nature. Any radio emission we do find, then, must result from either extremely low-level SF and/or AGN activity, or activity that is obscured in the optical. By observing how this emission behaves as a function of other SFR indicators, we will attempt to discern the origin (SF or AGN) of the radio flux, and, in the absence of AGN activity, the radio emission will give us a handle on the amount of star-formation occurring in these galaxies.

Salim et al. (2007) found that galaxies with no H α detectable in their SDSS spectra were mostly normal early-type galaxies with predominantly red optical colors, though some have relatively blue UV to optical colors (see also: Rich et al. 2005). They calculated that some of these galaxies had UV-derived SFRs as high as $1 M_{\odot} \text{ yr}^{-1}$, and a significant portion of those showed structure, like traces of faint spiral arms, or disturbed light profiles. They identified an evolutionary sequence from star-formation to quiescence via nuclear activity. Using a sample of nearby, early-type galaxies in the MOSES project (Morphologically Selected Ellipticals in SDSS), Schawinski et al. (2007) reached a similar conclusion. Yan et al. (2006) looked at optically-quiescent galaxies with red rest-frame colors and found that they were virtually indistinguishable in the color-magnitude-concentration space from galaxies classified as low-ionization nuclear emission-line regions (LINERs). Still, very little has been done on the radio properties of optically-quiescent galaxies, and we intend to use this relatively unexplored wavelength regime to add to our knowledge of such galaxies.

For the analysis of such faint radio sources, we have utilized the stacking technique presented in White et al. (2007), hereafter referred to as Paper I. This technique significantly reduces the noise in the combined images, allowing the investigation of median radio properties for sources significantly below the FIRST detection threshold without requiring countless more hours of telescope time. In addition, stacking all of the fields guarantees that the radio data will not be restricted by survey limits. In de Vries et al. (2007; hereafter, Paper II) we applied this method to the analysis of low-luminosity AGN, concluding that radio emission from star-formation can dominate over that due to the AGN emission in composite systems.

We begin by describing the radio data and the details of the sample selection (§2). We then go into the details of the stacking method (§3). In §4 we present our analysis and a detailed discussion of the results; §5 contains our

concluding remarks. Throughout this paper we use the standard FRW cosmology of $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_{\Lambda} = 0.7$, and $\Omega_M = 0.3$.

2. SAMPLE CONSTRUCTION

2.1. The Radio Data

The 1.4 GHz radio data we present are taken from the VLA FIRST Survey (Becker, White, & Helfand 1995), which includes $9,030 \text{ deg}^2$ sky coverage of the North Galactic Cap and Equatorial Strip, making it ideal for comparison with targets from the Sloan Digital Sky Survey (SDSS). With only $\sim 90 \text{ sources deg}^{-2}$ at the 5σ detection limit, 99.98% of the 5 billion beam areas are ‘blank’ (Paper I). The data, obtained from 180 sec VLA snapshots, have a typical rms of $0.15 \text{ mJy beam}^{-1}$. By stacking 3000 such snapshots, we can reduce the noise in the resultant image to approximately $3 \mu\text{Jy beam}^{-1}$ and achieve the sensitivity equivalent of 150 observing hours. To convert to rest-frame 1.4 GHz luminosity, we perform a k-correction assuming an average radio spectral index $\alpha = -0.5$. This index provides a compromise between steep-spectrum radio-lobe emission and flatter spectrum emission from the AGN cores or star-forming regions, and it is the same index adopted throughout Paper II.

2.2. The Quiescent Galaxy Sample

The sample of quiescent galaxies was drawn from the SFR Catalog of the MPA/JHU VACs (Brinchmann et al. 2004). The SFR catalog is a super-set of the galaxies discussed in Brinchmann et al. (2004) and contains all galaxies in the SDSS DR4 spectroscopic survey. DR4 of the SDSS has 6851 deg^2 of imaging and 4681 deg^2 of spectroscopic coverage. (See Adelman-McCarthy et al. (2006) for more information on DR4). Our final sample of quiescent galaxies is complete to a stellar mass lower limit of $10^8 M_{\odot}$. To accurately classify the objects, Brinchmann et al. reanalyzed the 1-D SDSS spectra using their own optimized pipeline as outlined in Tremonti et al. (2004). A galaxy was classified as either star-forming (SF), low S/N SF, AGN, low S/N AGN, Composite (C), or Unclassifiable based on the line ratios of the four emission lines described in Baldwin, Phillips, & Terlevich (1981, hereafter BPT). Composite galaxies have line ratios intermediate between SF and AGN. For the SF and low S/N SF classes, the fiber SFR was obtained from detailed modeling of the emission lines, while for the AGN, C, and Unclassifiable galaxies, the fiber SFR was estimated by calibrating the relation between the specific SFR (calculated for the star-forming galaxies) and the measured D4000 value as defined in Balogh et al. (1998). We will refer to the latter as “D4000” SFRs to differentiate them from SFRs obtained via emission lines. For both types, total SFRs were calculated using an empirically based aperture correction scheme based on the likelihood distribution of the specific star formation rate for a given set of colors (Brinchmann et al. 2004).

To single out only “quiescent” galaxies, we kept only those galaxies catalogued as Unclassifiable. The majority of this class are galaxies with no or very weak emission lines (Brinchmann et al. 2004). As the SDSS uses fiber-fed spectrographs, this is a ‘nuclear’ classification. The resultant sample contains $\sim 185,000$ quiescent galaxies.

FIG. 1.— A median image resulting from stacking 3000 quiescent LRGs. The image is $0.5' \times 0.5'$, (larger than normal, so the reader may observe the obvious sidelobes), and each pixel is $1.8''$ on a side. The cutouts comprising this image correspond to the galaxies making up the right-most circle in Figure 10, prior to being converted to radio luminosity. The image has a peak flux density of $90 \mu\text{Jy}$, with an rms of $6 \mu\text{Jy beam}^{-1}$. This image is virtually indistinguishable from any of the other high S/N images generated for this study, independent of the type of galaxy.

We obtain additional parameters of interest for each galaxy from the NYU Value-Added Galaxy Catalog (NYU-VAGC). As presented by Blanton et al. (2005), the NYU-VAGC is a collection of galaxy catalogs derived from the SDSS. The latest version of the catalog accompanies the SDSS DR4. We also make use of the derived ugriz absolute Petrosian magnitudes available in the associated catalog of K-corrections (Blanton et al. 2007). As these data were originally computed using a different value for the Hubble constant ($H_0 = 100$), we adjusted the derived absolute magnitudes to agree with the standard cosmology used elsewhere in this paper.

2.3. The Star-forming Galaxy and AGN Samples

The star-forming sample, first introduced in Paper II, consists of all galaxies classified as star-forming (SF) in the DR2 SFR catalog. This sample has $S/N > 3$ in all four emission lines of the BPT diagram and falls below the conservative threshold for AGN rejection. Star-formation rates quoted here were derived by Brinchmann et al. (2004) via careful modeling of the emission lines, and they take into account dust attenuation and fiber-corrections. Note that these SFRs assume a Kroupa IMF (Kroupa 2001). For absolute magnitudes and derived parameters, we consulted the Stellar Mass Catalog as presented by Kauffmann et al. (2003b).

The AGN sample was taken directly from Paper II and consists of objects from the Kauffmann et al. (2003a) AGN compilation. It should be noted that they use a more liberal AGN cut than Brinchmann et al. (2004), and this sample therefore consists of objects classified as AGN as well as those classified as Composite in Brinchmann et al. This is a simple naming-convention issue and does not affect our results. It is important to remember, however, that objects in the AGN sample are affected by star-formation to different degrees, with those closest to the cut having emission-line ratios more commonly associated with HII regions. We use the D4000 SFRs (as we do with the quiescent galaxies) from Brinchmann et al. (2004).

3. STACKING FIRST IMAGES

Using the sample selection criteria described above, we compiled our optically-selected quiescent galaxy sample. We then obtained 1.4 GHz data centered on each target position from the FIRST survey database. These square “cutouts” of the radio sky were $0.2'$ on a side and had the typical FIRST rms of $S_{rms} = 0.15 \text{ mJy beam}^{-1}$; these cutouts constitute our 3-D “image block”. The size of the images was chosen pragmatically based on limitations of IDL memory. Since all the analysis is based on the value of the central pixel, the image size is not important. In any case, all stacked images have a $\text{FWHM} \leq 8''$ and hence easily fit within the image format. These blocks can be sorted by a variety of parameters (e.g., redshift, color, SFR, etc.) and stacked to yield median radio flux density/luminosity as a function of the parameter of interest, with a bin size (N_{obj} / bin) determined by the radio survey depth required ($S_{min} \sim S_{rms} / \sqrt{N}$).

Bins typically contained either 1500 or 3000 images each. The median of the parameter of interest was determined for each bin. To obtain the associated radio luminosity, the cutouts were processed through an IDL procedure which converted each individual image to units of radio luminosity using the target galaxy’s measured redshift (Paper I) and then output the median image and $\pm 1\sigma$ upper/lower bounds for each pixel. The basic algorithm for determining the error bars involved computing the probability that the true median lay between elements (k,k+1) in the sorted image stack using binomial probabilities as described in Gott et al. (2001). As these sources are all quite faint in the radio, we will simply quote the radio luminosity derived from the central pixel in each co-added image as done in Paper I.

The median was used as opposed to the mean because it is more statistically robust in the presence of outliers and/or contamination. For example, Salim et al. (2007) note that $\sim 2\%$ of the unclassifiable galaxies have line emission, some quite significant. The median will be little changed by a 2% contaminant. The mean, on the other hand, is sensitive not only to outliers, but also to the threshold values imposed to try to weed out those outliers (Paper I). When we used means, we found the radio luminosities all increased by 1-2 orders of magnitude. That being said, the interpretation of the median is slightly more complicated. The median shifts toward the ‘local’ mean in the case of low S/N data. (See Paper I for a more detailed discussion).

Once the radio data were stacked, we corrected for the so-called ‘snapshot bias’. This phenomenon is somewhat analogous to the ‘CLEAN bias’ reported for the FIRST and NVSS surveys, where the result of the non-linear CLEAN algorithm is that a small amount of flux from the above-threshold sources is redistributed over the field (Becker, White, & Helfand 1995; Condon et al. 1998). A similar bias for sub-threshold sources (that have therefore never been CLEANed) was discovered and calibrated in Paper I. For sources fainter than 0.75 mJy , only 71% of the true mean flux density is recovered per bin, while sources above 0.75 mJy are well-described by the addition of a constant 0.25 mJy CLEAN bias. Since the majority of the target galaxies in this study are sub-threshold, we accounted for this snapshot bias via the constant multiplicative factor of 1.40.

FIG. 2.— A plot of radio flux density versus apparent magnitude for the entire quiescent galaxy sample. The median-stacking method allows us to probe flux density levels down to the 10s of μJy . The clear selection bias toward stronger radio sources is evident below $m_z \sim 17$; this is a result of the SDSS target selection algorithm (see text).

FIG. 3.— A plot of radio flux density versus apparent magnitude for the quiescent galaxy sample, this time with galaxies targeted as part of the MAIN Galaxy Sample plotted separately from those targeted as LRGs. The LRGs have much higher median flux densities.

An example of a median-stacked image is shown in Figure 1. The image is $0.5'$ on a side and resulted from stacking 3000 quiescent LRGs. The cutouts that went into this image were the flux density maps of the galaxies that were later converted to units of luminosity and stacked to give the right-most quiescent LRG bin (circle) in Figure 10. The image peaks at $90 \mu\text{Jy}$ and has an rms of $6 \mu\text{Jy beam}^{-1}$.

4. RESULTS

4.1. Quiescent Galaxy Sample Selection Effects

In order to explore the radio emission of the quiescent galaxy sample, we used the median-stacking technique detailed in §3. Typical radio flux density levels attainable via this method are shown in the plot of flux density vs. apparent magnitude (z -band) in Figure 2. Each point is the result of median-stacking 3000 quiescent galaxies. As Figure 2 demonstrates, a pronounced selection effect becomes apparent when the data are represented in this manner. This effect is the result of the SDSS target selection algorithm which includes different samples; the MAIN Galaxy Sample, the Luminous Red Galaxy (LRG)

FIG. 4.— Radio Luminosity (1.4 GHz) vs. optically-derived SFR from Brinchmann et al. (2004). This plot shows the star-forming galaxies and AGN originally presented in Paper II, as well as the quiescent MAIN sample galaxies and LRGs overplotted. Note that all of these objects are still at least 3 orders of magnitude fainter than the typical radio-loud object.

sample, and the Quasar, Star, or Serendipity samples (Stoughton et al. 2002). Galaxy targets are selected for inclusion in the SDSS MAIN galaxy sample if they satisfy a number of criteria outlined in detail in Strauss et al. (2002). Approximately 55% of our sample of quiescent galaxies were targeted as part of the MAIN Galaxy sample. The remaining 45% of our quiescent sample, save a small percentage of miscellaneous objects which we discarded, were targeted as part of the LRG sample. As described by Eisenstein et al. (2001), the LRG sample extends to higher z and to fainter magnitudes than the MAIN galaxy sample and consists of objects that are luminous ($L > 3L_*$) and intrinsically very red.

Objects may also have more than one target flag set at a time. Of particular concern to us are those objects targeted for both the MAIN and LRG samples. Since the LRG group is generally more restrictive, and for reasons that will become apparent in our §4, we have chosen to keep these objects with the LRGs rather than the MAIN galaxy sample. As advised in Eisenstein et al. (2001), we then keep only those objects with the GALAXY_RED flag set and redshifts $z > 0.2$. These further restrictions account for the breakdown of the luminosity cut at lower redshifts and ensure the purity of the LRG sample.

If the data are first segregated into MAIN galaxies and LRGs, a rather different picture emerges. Figure 3 again shows flux density vs. z -band apparent magnitude, but this time the sources targeted as part of the MAIN Galaxy Sample are plotted as diamonds, while those targeted as part of the LRG sample are plotted as crosses. The MAIN Galaxy Sample show typical radio flux densities in the 10s of μJy , with an increasing number of Southern Equatorial Strip sources comprising the low-magnitude tail. Of these galaxies, fewer than 0.1% were found to be coincident with cataloged FIRST sources. The LRGs have significantly higher median radio flux density levels (though still far below the FIRST threshold for detection) and exhibit a trend toward lower flux densities with increasing magnitude. Out of the LRG sample, 0.9% are found to be within $2''$ of a source in the FIRST catalog, a detection rate nearly ten times that of the MAIN Galaxy Sample.

4.2. Radio Luminosity as a Proxy for Star-Formation

As mentioned in the Introduction, radio emission can be used as a tracer of star-formation for galaxies with no contaminating nuclear activity. We use the star-forming galaxy sample, described in Section 2, to obtain the relationship between star-formation rate and radio luminosity. The SF galaxies have measured SFRs based on $H\alpha$ and other optical emission lines, and we sorted the sample by this “ $H\alpha$ -derived” SFR and binned/stacked the data using the method outlined in Section 3. The result, published in Paper II and repeated in Figure 4, shows a tight correlation between radio luminosity and SFR for the SF galaxies which extends over more than two orders of magnitude in SFR. The least-squares fit to the data gives $\log(L_{1.4}) = (1.37 \pm 0.02) \log(\text{SFR}) + (27.67 \pm 0.01)$.

There have been a number of studies deriving SFR from 1.4 GHz emission, many of which use the radio-SFR relation presented by Condon (1992). This relation, and those like it (Yun et al. 2001) assume a linear relationship between SFR and radio luminosity. Indeed, the tightness of the radio-FIR correlation was first interpreted as evidence for a linear relationship. However, several authors (Price & Duric 1992; Bell 2003) have shown that the synchrotron component, which generates $\sim 90\%$ of the emission at 1.4 GHz, depends non-linearly on the SFR. Price & Duric (1992) found that, by decomposing the radio emission in the radio-FIR relation into thermal bremsstrahlung and non-thermal synchrotron components, the non-thermal radio luminosity scaled as $(\text{SFR})^{1.2}$, even while the thermal emission was directly proportional to SFR. Bell (2003) argued that the radio-FIR correlation is a conspiracy resulting from the non-linearity of both SFR indicators. They find that $L_{1.4}$ goes as $(\text{SFR})^{1.3}$, a result which is very close to our derived power-law dependance of 1.37.

4.3. Radio Emission from Quiescent Galaxies

Figure 4 shows our results for the quiescent galaxies overplotted on the SF galaxies and AGN of Paper II. The first thing to notice is the large difference between the behavior of the MAIN and LRG-targeted samples. Keeping in mind that the LRG bins do have significantly higher median redshifts than the MAIN galaxy bins, the samples nevertheless exhibit very different trends. The LRG sample maintains relatively constant median radio luminosity even with optically derived SFRs (from D4000) varying from 0.1 to 10 $M_{\odot} \text{ yr}^{-1}$, suggesting that the radio emission from these optically-normal LRGs is dominated by AGN activity rather than star-formation. I.e., if some of the radio luminosity came from star-formation, there would be a dependance on SFR. Indeed, for LRGs with $\text{SFR} < 1 M_{\odot} \text{ yr}^{-1}$, less than 1% of the radio flux should originate from SF activity. It has been pointed out to us that perhaps the SFRs in the MPA/JHU catalog were never intended to be appropriate for the LRGs in the catalog, seeing as they derived from star-forming galaxy colors and reach quite spectacular rates for galaxies believed to be red and dead. This does not change our result. Whether the LRG SFRs are in the ballpark or complete nonsense, the median radio luminosity of the sample is simply too high to be attributable to SF alone.

One may ask how LRGs actually classified as AGN

compare. We therefore compiled a sample of galaxies classified as AGN or Composite from the MPA/JHU SFR catalog that were also targeted as LRGs. We found only ~ 600 such galaxies, not even enough for a full bin and not nearly enough to examine trends in the stacked behavior. The partial bin we were able to make lies basically right on top of the quiescent LRGs, with a median SFR of $\sim 4 M_{\odot} \text{ yr}^{-1}$ and an L_R of $10^{29.9} \text{ ergs s}^{-1} \text{ Hz}^{-1}$.

Figure 4 therefore provides evidence that quiescent LRGs host AGN, a result that has some interesting implications. Most current models of cosmic structure formation include AGN feedback, and both radiative and mechanical heating of the “radio mode” AGN are now recognized as important in galaxy formation scenarios (for e.g., Croton et al., 2006, and Granato et al., 2004). As radio emission from black holes often indicates the presence of jets, these data lend observational support to the existence of a mechanism for low-level feedback in these galaxies. In addition, this result also gives a quantitative feel for the feedback subsequently implied. The constant median value of $L_R \sim 4 \times 10^{29} \text{ ergs s}^{-1} \text{ Hz}^{-1}$ radiated by these quiescent LRGs, while still technically low-luminosity, is over two orders of magnitude larger than that attributed to the “ground state” of the optically-detected low-luminosity AGN in Paper II. As to why the LRGs are so much more radio-luminous, perhaps this is evidence that more massive AGNs are more radio-luminous. But speculation aside, it is true that here we are dealing with median statistics and therefore have no knowledge of the underlying luminosity distribution (i.e., whether it is bimodal, etc.). We also cannot say whether the spread in the distribution is due to time variability or static differences between galaxies. However, by treating this value of radio luminosity as a time-average (rather than ensemble-average), we get an estimation of the average luminosity of radio jets which may result in AGN feedback in LRGs.

We now turn our attention to the MAIN sample galaxies in Figure 4. These galaxies show a trend in radio luminosity with SFR which intersects the SF sample around $1 M_{\odot} \text{ yr}^{-1}$. The agreement is worse for higher values of SFR, where the MAIN sample galaxies deviate systematically from the SF galaxies by a little over a factor of 3. There are two competing theories for the origin of the radio emission from these galaxies: that it is due to SF, or that it is due to AGN activity. The fact that L_R shows a dependence on D4000 SFR, and that it disagrees with the SF sample by no more than a factor of 3 over the whole range of SFRs, suggests that it may arise in part from star-formation. Alternatively, one may argue we are seeing the results of a correlation between L_R and mass that is due to AGN activity, a valid argument that we elaborate on below. However, since the L_R is near the level of the SF galaxies, we think it only fair to entertain the notion that it is due to SF. If we assume this to be the case, the disagreement between the MAIN sample and SF galaxies may be an artifact of the different methods (D4000 vs. emission lines) used by Brinchmann et al. (2004) to measure SFRs for the different samples. Although Brinchmann et al. (2004) proved the reliability of these D4000 values for galaxies in the star-forming regions of the BPT diagram, that doesn’t guarantee that the calibration yields spot-on values for galaxies with suppressed emission lines. Salim et al. (2007) argue that

FIG. 5.— Composite spectra for the MAIN sample quiescent galaxies. The top panel (a) shows the composite spectrum for the 3000 galaxies comprising the bin with the lowest SFR in Figure 4, while the bottom panel (b) shows that of the bin with the highest SFR. The insets show the spectral features associated with OII, $H\alpha$, and NII.

the D4000 - specific SFR calibration and the color-based aperture corrections are only completely accurate for the SF galaxies, since both methods are dependent on time-scale and other galaxy types have different star-formation histories.

The wary critic might ask whether D4000 is measuring star-formation at all in this case, or whether AGN emission is contaminating the D4000 break as well, leading to overestimation of the D4000 SFRs for the MAIN sample. We have considerable reason to believe that this, at least, is not the case. For one thing, the absence of observable line emission from the AGN makes it unlikely that the AGN would contribute significantly to the continuum near the 4000 Å break. And furthermore, even for optically-detected AGN, Kauffmann et al. (2003a) showed that the AGN contribution to the blue continuum is ignorable.

To get a better feel for these objects, we take advantage of our large sample size and examine trends in median-stacked spectra. We have created median composite SDSS spectra for both the MAIN galaxy sample and the LRGs as a function of SFR bin as shown in 4. These spectra, normalized such that the continuum value at 4000 Å is unity, are shown in Figures 5 and 6, respectively. In each case, the top panel shows the spectrum for the lowest SFR bin and the bottom shows that of the highest SFR bin. We should note that we also

FIG. 6.— Composite spectra for the quiescent LRG sample. The top panel (a) shows the composite spectrum for all the galaxies comprising the bin with the lowest SFR in Figure 4 as calculated from D4000, while the bottom panel (b) shows that of the bin with the highest SFR. The insets show the spectral features associated with OII, $H\alpha$, and NII.

FIG. 7.— [OII] Luminosity vs. SFR for the quiescent MAIN and star-forming galaxy samples. Values for [OII] Luminosity are rough estimates using the conversion from equivalent width to luminosity in Kennicutt (1992) with median g' -band luminosity.

tried binning spectra by SDSS z-band absolute magnitude, and the resulting composite spectra had line emission no more obvious than those spectra binned by SFR that we show here.

These high S/N composite spectra clearly show very weak emission features. They do, however, show strong Balmer line absorption; strong enough to plausibly swal-

FIG. 8.— Radio Luminosity (1.4 GHz) vs. $u-r$ color for a volume-limited subsample of the quiescent MAIN galaxy sample. Since the fraction of diluted AGN increases with redshift (Reviglio & Helfand 2007), the radio luminosity might be expected to increase if misclassified AGN dominate the radio emission.

low most of the $H\alpha$ emission. This is supported by some [NII] emission even in the absence of $H\alpha$. The inset of Figure 5b shows a zoomed-in view of this region for the high-SFR galaxies in the MAIN sample. $H\alpha$ emission is just visible over the accompanying deep absorption feature. Some may argue that the [NII]/ $H\alpha$ ratio is more easily explained by a LINER (low ionization emission-line region) spectrum, and this may well be the case. However, there is also an obvious turn-up below ~ 3300 Å in the spectrum of the high-SFR MAIN galaxies, and no sign whatsoever of a similar trend in the low-SFR MAIN galaxies or LRGs.

For both samples, the spectra with higher median SFRs show greater [OII] emission, a useful proxy for star-formation in the absence of $H\alpha$ (Kennicutt 1992). (We should note, however, that Yan et al. (2006) found [OII] emission in red and post-starburst galaxies can be as strong as in star-forming galaxies.) We have attempted to quantify this result for the MAIN sample galaxies in Figure 7. The [OII] Luminosities on the vertical axis were calculated by determining the equivalent widths and using the conversion to luminosity given in (Kennicutt 1992). They are only rough estimates, however, as we used magnitude in the g' -band rather than the B-band, and we used the median magnitude for the conversion of the composite equivalent width. For comparison, we also plot the results for the Star-forming sample. The [OII] Luminosities for the MAIN sample do increase with SFR, but only weakly relative to the Star-forming sample. If we assume the [OII] in the quiescent MAIN sample traces SF just as reliably as in the SF sample, and if we use the SF galaxies to calibrate an [OII]-SFR relation, the implied SFRs are all $\leq 1 M_{\odot} \text{ yr}^{-1}$. There also appears to be a kink around $1 M_{\odot} \text{ yr}^{-1}$, the same point at which the radio luminosities diverge, prompting speculation of a change in population at that point. Regardless, the weakness of the [OII] dependence on D4000 SFR may indicate that both SF and AGN activity are contributing to the line emission, with the AGN component dominating. Of course, why these galaxies have such weak line emission has been the question all along, and it pertains to both AGN and SF.

The real question here is which component (AGN or SF) dominates the radio emission, and we do

FIG. 9.— Radio Luminosity (1.4 GHz) vs. z -band Absolute magnitude for quiescent and star-forming galaxies. Arrows indicate upper limits. The star-forming galaxies have been split into 4 bins based on their fiber-corrected star-formation rates, and the median SFRs and [SFR ranges] are shown in the legend. We fit a line to the quiescent galaxy data; the least-squares fit gives $\log(L_R) = (-0.92 \pm 0.02)M_z + (7.5 \pm 0.4)$. Additional error bars are overplotted on the star-forming galaxy points. These larger error bars correspond to 10% / 90% of the SFR dispersion for the galaxies within each bin.

not believe that these composite optical spectra alone can answer that question. In a recent paper, Magliocchetti, Andreani, & Zwaan (2007) use a sample of optically obscured, 24- μm -selected galaxies observed by Spitzer in the First Look Survey (FLS) to conclude that the 1.4 GHz luminosity is dominated by star-formation activity despite the presence of an AGN component. IRAC photometry sets the majority (66%) in a redshift interval of $z = 1-3$. The same conclusion was drawn in Paper II for optically classified AGN/Composites in the local universe with $\text{SFR} > 1 M_{\odot} \text{ yr}^{-1}$.

If AGN activity is the source of the radio emission from the MAIN galaxy sample, then one possible explanation for the weak line emission is dilution. It has been shown that stellar continuum light of a host galaxy may dilute the nuclear emission lines of an AGN and hinder its detection (Moran, Filippenko, & Chornock 2002). Reviglio & Helfand (2007) present evidence that this effect leads to an increasing number of misclassified weak-lined AGN with increasing redshift in the SDSS and other redshift surveys. We test for this effect in Figure 8, where we take a volume-limited subsample in a narrow optical luminosity range and assess the effect of redshift on radio luminosity versus $u-r$ color. Note that the magnitude cut of $-22 < M_z < -23$ has preferentially selected the more luminous galaxies (in the radio as well as the optical). If increasing redshift bins show larger luminosities, we might conclude that AGN are contributing significantly to the radio emission. While there seems to be a slight trend, the effect is quite small and the error bars are large. The null result is therefore inconclusive.

If the radio emission of the MAIN galaxy sample stems from star-formation, dilution might still be the culprit. To test this theory, we plot radio luminosity versus z -band absolute magnitude for the quiescent and star-forming galaxy samples in Figure 9. The SFR axis on the right-hand side of this figure (and those that follow) utilizes the radio-SFR calibration equation obtained in the previous section using the star-forming galaxy sample.

FIG. 10.— Radio Luminosity (1.4 GHz) vs. z-band absolute magnitude for quiescent MAIN sample galaxies and LRGs. SFRs from Brinchmann et al. (2004) are overplotted for each bin of both samples.

FIG. 11.— Same as Figure 9, but with UV-derived SFRs from GALEX overplotted for each point as open squares. Though the UV-derived SFRs and the D4000 SFRs are discrepant by 1-2 orders of magnitude for the MAIN galaxies, we find them to be tightly correlated, arguing for a common origin.

If we suppose for the moment that the radio emission of the Main sample quiescent galaxies originates with star-formation, then we can apply it to these galaxies as well (it obviously does not apply to the LRGs given our above results). We derived the mass (upper) axis from a linear least-squares fit to the plot of $\log(\text{stellar mass})$ versus M_z , where the masses came from the Stellar Mass Catalog (Kauffmann et al. 2003b). The star-forming galaxy sample was first sorted by SFR and split into 4 subgroups to aid in the interpretation of the quiescent galaxy SFRs. The median SFRs and ranges in median SFR for the bins in a particular subgroup are shown in the legend. The stacks were reduced to 1500 objects per bin to allow for an adequate number of data points in each subgroup, and the resultant subgroups are plotted as different symbols for easy differentiation. The data for the LRG and MAIN samples were binned and stacked following our standard procedure, with the error bars representing $\pm 1\sigma$ in median radio luminosity. We find that the quiescent MAIN sample follow a power-law fit of $\log(L_R) = (-0.92 \pm 0.02)M_z + (7.6 \pm 0.5)$.

While the $H\alpha$ -based method does yield a large overall range of star-formation rates, the SF sample display a narrow range of SFRs for a given absolute magnitude of

the host galaxy. This result was previously confirmed by Salim et al. (2007). If we assume no AGN contamination for the moment, then using stacked radio luminosity as an indicator yields SFRs for the quiescent MAIN galaxies that are consistently 3-5 times lower than the SF galaxies. Keep in mind that we are not suggesting that the quiescent MAIN sample galaxies are intrinsically the same as the line-emitting SF galaxies, which we already demonstrated to populate a tight sequence in $\text{SFR}-M_z$ space. But if we are to believe the trend demonstrated in Figure 4, particularly for the low- L_R end, then one interpretation is that the strength of $H\alpha$ needed for detection (and for subsequent SFR-estimation) is proportional to absolute magnitude. This interpretation implies a sort of $H\alpha$ -dilution. To illustrate this point further, we have taken the star-forming galaxies in Figure 9 and overplotted larger error bars representing the 10% / 90% range in SFR dispersion for the galaxies comprising each data point.

Figure 10 uses the same axes to show how the radio-derived star-formation rates for the quiescent galaxies compare to those available from Brinchmann et al. (2004) in a different way than Figure 4. The 8-point stars still represent the quiescent galaxies targeted in the MAIN Galaxy Sample, while the objects in the LRG sample are shown as open circles in the upper left-hand region of the plot. We have then overplotted (as crosses and squares, respectively) the median optically-derived SFR for each bin using the SFR axis on the right-hand side of the plot. For the quiescent LRG sample, the D4000 SFRs are roughly two orders of magnitude lower than those inferred from the radio data; i.e., there is excess radio emission over that which is attributable to star-formation. This is again consistent with the hypothesis that the radio emission from these LRGs is dominated by AGN activity.

The data for the MAIN sample quiescent galaxies show somewhat better agreement. The D4000 SFRs for the MAIN sample overlap the radio-derived SFRs at a few $M_\odot \text{ yr}^{-1}$ and an absolute magnitude of $M_z = -22.5$, though the two estimates show different slopes with absolute magnitude. If the quiescent MAIN sample are star-forming, this discrepancy could simply be explained by the different methods used to calculate SFR between SF and “Unclassifiable” galaxies. If the emission is dominated by an AGN contribution, alternatively, it must scale with galaxy stellar mass to explain the observed correlations. This is not surprising for star formation in a homogenous sample of galaxies, but one might argue that this is expected for AGN as well, given the well-known scaling relation between black hole mass and bulge luminosity (Kormendy & Richstone 1995; Ferrarese & Merritt 2000). Our own results for the quiescent LRGs may even support this claim.

As we have discussed above, radio emission is an indirect indicator of star-formation. The UV continuum, on the other hand, is thought to be directly proportional to the photospheric emission of young stars (Kennicutt 1998). Still, it is not free from problems of its own, most notably significant dust obscuration. Nevertheless, as another comparison, we overplot UV-derived SFRs from GALEX (Salim et al. 2007) in Figure 11, corrected to our IMF. As our samples do not completely overlap, we have simply taken the median of the UV SFRs available

for each bin. For our MAIN sample quiescent galaxies, there were generally ~ 300 galaxies (per 3000-galaxy bin) with UV SFRs, and we find these galaxies to have fairly representative radio luminosities (i.e., there is no selection bias between our samples). None of the quiescent galaxies targeted as LRGs had UV-SFRs available from this catalog.

These UV-based SFRs were obtained by Salim et al. (2007) via SED-fitting of emission from the UV to the z-band with various models from the Bruzual & Charlot (2003) population synthesis code. Because the UV luminosity imposes the tightest constraint on the SFR, the authors refer to these SFRs as “UV-derived”. Their quoted rates are averaged over a span of 100 Myr and constitute the first test of the two-component dust attenuation model proposed by Charlot & Fall (2000). Salim et al. (2007) compare these rates with the optically-derived rates for the Brinchmann et al. (2004) star-forming sample and report good overall agreement, with some systematic deviation due to differences in modeling dust attenuation. It is therefore not surprising that we also find good agreement in the star-forming sample, as they are derived from the same catalog and served as our radio-SFR calibrators.

The interpretation of the UV and radio-derived SFRs for the MAIN sample quiescent galaxies is, once again, less straightforward. The UV-derived SFRs are between 2-3 orders of magnitude lower than the SFRs derived from radio-stacking. Given the rough agreement of the radio and D4000 SFRs, it is then no surprise that Salim et al. (2007) find a ~ 2 order-of-magnitude discrepancy for the UV versus optically-derived SFRs of their “No H α ” sample, which comprise roughly $\sim 10\%$ of our total MAIN quiescent sample. They conclude that, since these galaxies fall largely on the red sequence, the UV SFRs are more realistic. Another of their arguments is that such high SFRs as Brinchmann et al. (2004) estimate would result in a large fraction of their “No H α ” galaxies having detectable H α . On the contrary, we have shown in Figure 9 that this result could also be explained if the strength of H α required to constitute a “detection” is simply a function of optical luminosity, with the levels predicted for these quiescent galaxies falling below the detection limit for a given absolute magnitude.

The strongest argument for the UV-SFRs is that the 2-3 orders of magnitude discrepancy between the radio and UV would require an underestimation of dust extinction of 5-8 magnitudes. This is, admittedly, quite large, but perhaps the disagreement between SFR estimates could be explained by the location of the star-formation; If the star-formation is dominated by nuclear star-formation, it might be easier to hide both the line-emission and the UV flux from observation. This is speculative, but we would like to emphasize again that the radio emission and D4000 index are two independent checks on the presence of star-formation, and they are consistent with one another to within a factor of ~ 3 . While they both can be higher than the true SFR for completely different reasons, we feel this is a coincidence that requires further explanation before the possibility of SF in these galaxies can be thrown out altogether. We will, however, freely acknowledge that if the GALEX SFRs are right, then for sure the radio-derived SFRs are due to AGN activity. Overall, whether this discrepancy is ultimately the result

of an AGN component to the radio emission or a poor dust-attenuation model is not a question we feel can be definitively answered here.

5. CONCLUSIONS

We have investigated the radio emission from a sample of $\sim 185,000$ optically-selected quiescent galaxies from the Sloan Digital Sky Survey. By stacking FIRST cutouts centered on the galaxy positions, we reach median radio flux densities down to the 10s of μJy . We calibrate the relation between 1.4 GHz radio emission and optically-derived SFR using a sample of star-forming galaxies, allowing us to look for star-formation in their quiescent counterparts. The main findings of this study are summarized below.

- We find a tight correlation between radio luminosity and SFR for the star-forming galaxy sample, with $L_{1.4\text{GHz}}$ going as $(\text{SFR})^{1.37}$.
- The quiescent galaxy sample consists of two subgroups: those targeted as part of the MAIN Galaxy Sample, and those targeted as part of the Luminous Red Galaxy (LRG) Sample. The former show partial overlap with the star-forming sample on a plot of L_R vs. optically-derived SFR, while the latter show a relatively constant, high value of median radio luminosity that does not vary with SFR.
- For the LRGs, the correspondingly high rates of radio-derived star-formation conflict with those estimated by Brinchmann et al. (2004) via calibration of the 4000-Å break by two orders of magnitude on a plot of derived-SFR vs. M_z . This result, combined with the relative constancy of L_R with D4000 SFR, suggests that the radio emission of these quiescent LRGs derives not from star-formation but from an AGN component. This implies the possible presence of radio jets and a mechanism for low-level feedback in these galaxies.
- The MAIN sample galaxies, on the other hand, exhibit a L_R -SFR trend which intersects the SF sample around $1 M_\odot \text{ yr}^{-1}$ and deviates by no more than a factor of 3 over the whole range of SFRs. This agreement as well as the dependence of L_R with SFR suggests that the L_R might arise in part from star-formation (particularly in so far as the AGN of Paper II show no such dependence.) If we assume the radio emission of these galaxies originates from star-formation, the deviation at high/low values of SFR might then be due to the different diagnostic measures used to estimate SFR for the two samples (i.e., 4000-Å break vs. emission-lines). However, we cannot rule out the possibility that the radio emission may have a large or even dominant AGN component, with a L_R -mass relation causing the observed correlation.
- Composite spectra of the MAIN sample show Balmer absorption strong enough to plausibly swallow any H α emission present. This is supported by some [NII] emission even in the absence of H α . The [OII] emission, however, increases only slightly

with D4000 SFR, giving reason to doubt the validity of D4000 (and thus radio emission) as a proxy of star-formation in these galaxies until we understand why the line emission is so highly-suppressed.

- The MAIN quiescent sample shows a correlation between radio luminosity and z-band absolute magnitude of the form: $\log(L_{1.4}) = (-0.92 \pm 0.02)M_z + (7.6 \pm 0.4)$. The SFRs implied by radio emission reach above $10 M_\odot \text{ yr}^{-1}$, yet lie just below the objects classified as “star-forming” for a given absolute magnitude. If we assume the radio emission stems from SF, one possible interpretation is that the strength of the optical emission lines needed to constitute a “detection” varies with galaxy luminosity, and using our radio-stacking method allows us to probe low levels of star-formation despite SF dilution in the optical. If we assume the radio emission stems from AGN activity, then both the D4000 and radio-derived SFRs are too high (for separate reasons), and the observed trend implies a relation between AGN radio luminosity and galaxy mass.
- UV-derived SFRs from GALEX are 2-3 orders of magnitude lower than the SFRs predicted by radio-stacking for the MAIN quiescent galaxy sample. This indicates possible AGN contamination in the radio emission of the quiescent galaxies, incomplete modeling of the dust attenuation for the UV emission, or both. The different processes at play obviously need to be better understood before we can choose the most useful SFR diagnostic tool for these optically-quiescent galaxies.

In short, we use a novel stacking technique to provide strong evidence that quiescent LRGs harbor AGN. This result has clear implications for galaxy formation scenarios, providing observational support to the existence of a mechanism for low-level feedback in these galaxies. The results for the quiescent MAIN sample galaxies are more nebulous, with the discrepancies between the different SF indicators clearly highlighting how much we still have to learn about these persistently unclassifiable galaxies. Overall, we believe the technique utilized

here shows great promise as a tool to investigate further the radio emission of various sub-populations in the vast community of radio-quiet galaxies.

The authors wish to thank David Helfand for sparking such lively discourse and being a champion of the championless (views, that is). They also wish to thank Samir Salim for kindly providing the UV data and taking the time to craft such a careful critique of the paper. JAH acknowledges support of the GAANN Fellowship from the U.S. Department of Education, as well as a UC Davis Graduate Block Grant Fellowship, and Grant HST-GO-10412.03-A from the Space Telescope. RHB acknowledge the support of the National Science Foundation under grant AST 00-98355. RLW acknowledges the support of the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy under NASA contract NAS5-26555. The work by WDV and RHB was partly performed under the auspices of the U.S. Department of Energy, National Nuclear Security Administration by the University of California, Lawrence Livermore National Laboratory under contract No. W-7405-Eng-48.

Funding for the Sloan Digital Sky Survey (SDSS) has been provided by the Alfred P. Sloan Foundation, the Participating Institutions, the National Aeronautics and Space Administration, the National Science Foundation, the U.S. Department of Energy, the Japanese Monbukagakusho, and the Max Planck Society. The SDSS Web site is <http://www.sdss.org/>.

The SDSS is managed by the Astrophysical Research Consortium (ARC) for the Participating Institutions.
